(Dated: November 18, 2016)

We perform three-dimensional numerical relativity simulations of homogeneous and inhomogeneous expanding spacetimes, with a view towards quantifying non-linear effects from cosmological inhomogeneities. We demonstrate fourth-order convergence with errors less than one part in 10^6 in evolving a flat, dust Friedmann-Lemaître-Robertson-Walker (FLRW) spacetime using the Einstein Toolkit within the Cactus framework. We also demonstrate agreement to within one part in 10^3 between the numerical relativity solution and the linear solution for density, velocity and metric perturbations in the Hubble flow over a factor of ~ 350 change in scale factor (redshift). We simulate the growth of linear perturbations into the non-linear regime, where effects such as gravitational slip and tensor perturbations appear. We therefore show that numerical relativity is a viable tool for investigating nonlinear effects in cosmology.

I. INTRODUCTION

Modern cosmology relies on the cosmological principle — that the Universe is sufficiently homogeneous and isotropic on large scales to be described by a Friedmann-Lemaître-Robertson-Walker (FLRW) model. Cosmological N-body simulations [e.g. 1–3] encode these assumptions by prescribing the expansion to be that of the FLRW model, governed by the Friedmann equations, while employing a Newtonian approximation for gravity.

The transition to cosmic homogeneity begins on scales $\sim 80h^{-1}$ Mpc [e.g. 4, 5], but is inhomogeneous and anisotropic on smaller scales. Upcoming cosmological surveys utilising Euclid, the Square Kilometre Array (SKA) and the Large Synoptic Survey Telescope (LSST) [6–8] will reach a precision at which nonlinear general relativistic effects from these inhomogeneities could be important. A more extreme hypothesis [9–20] is that such inhomogeneities may provide an alternative explanation for the accelerating expansion of the Universe, via *backreaction* [see 21, 22, for a review], replacing the role assigned to dark energy in the standard Λ CDM model [23–26].

Quantifying the general relativistic effects associated with nonlinear structures ultimately requires solving Einstein’s equations. Post-Newtonian approximations are a worthwhile approach [27–36], however the validity of these must be checked against a more precise solution since the density perturbations themselves are highly nonlinear.

An alternative approach is to use numerical relativity, which has enjoyed tremendous success over the past decade [37–39]. Cosmological modelling with numerical relativity began with evolutions of planar and spherically symmetric spacetimes using the Arnowitt-Deser-Misner (ADM) formalism [40], including Kasner and matter-filled spacetimes [41], the propagation and collision of gravitational wave perturbations [42, 43] and linearised

perturbations to a homogeneous spacetime [44, 45]. More recent work has continued to include symmetries to simplify the numerical calculations [e.g. 46, 47].

Simulations free of these symmetries have only emerged within the last year. Giblin et al. [48] studied the evolution of small perturbations to an FLRW spacetime, exploring observational implications in [49]. Bentivegna and Bruni [50] showed differential expansion in an inhomogeneous universe, and quantified the backreaction parameter from [51] for a single mode perturbation. These works all indicate that the effects of nonlinear inhomogeneities may be significant.

In this work, we perform a feasibility study of numerical solutions to the full Einstein equations for inhomogeneous cosmologies by simulating the growth of structure in a model three-dimensional universe and comparing to known analytic solutions. Our approach is similar to [48–50], with differences in the generation of initial conditions and numerical methods. We use the freely-available Einstein Toolkit, based on the Cactus infrastructure [52, 53]. We benchmark our three-dimensional numerical implementation on two analytic solutions of Einstein’s equations relevant to cosmology: FLRW spacetime and the growth of linear perturbations. We also present the growth of perturbations into the nonlinear regime, and analyse the resulting gravitational slip [54, 55] and tensor perturbations.

In Section II we describe our numerical methods, including gauge choices (II A) and an overview of the derivations of the linearly perturbed Einstein equations used for our initial conditions (II B). In Section III we describe the setup (III A) and results (III B) of our evolutions of a flat, dust FLRW universe. The derivation of initial conditions for linear perturbations to the FLRW model are described in IV A, with results presented in IV B. The growth of the perturbations to nonlinear amplitude is presented in V, with analysis of results and higher order effects in V A and V B respectively. We adopt geometric units with $G = c = 1$, Greek indices run from 0 to 3 while Latin indices run from 1 to 3, with repeated indices implying summation.

II. NUMERICAL METHOD

We integrate Einstein’s equations with the Einstein Toolkit, a free, open-source code for numerical relativity [52]. This utilises the Cactus infrastructure, consisting of a central core, or “flesh”, with application modules called “thorns” that communicate with this flesh [56]. The Einstein Toolkit is a collection of thorns for computational relativity, used extensively for simulations of binary neutron star and black hole mergers [e.g 57–59]. Numerical cosmology with the Einstein Toolkit is a new field [50]. We use the `McLachlan` code [60] to evolve spacetime using the Baumgarte-Shapiro-Shibata-Nakamura (BSSN) formalism [61, 62], and the `GRHydro` code to evolve the hydrodynamical system [59, 63, 64]; a new setup for cosmology with the Einstein Toolkit.

We use the fourth-order Runge-Kutta method, adopt the Marquina Riemann solver and use the piecewise parabolic method for reconstruction on cell interfaces. `GRHydro` is globally second order in space due to the coupling of hydrodynamics to the spacetime [64, 65]. We therefore expect fourth-order convergence of our numerical solutions for the spatially homogeneous FLRW model. Once perturbations are introduced to this model we expect our solutions to be second-order accurate.

We have developed a new thorn, `FLRWSolver`, to initialise an FLRW cosmological setup with optional linear perturbations. We evolve our simulations in a cubic domain on a uniform grid with periodic boundary conditions with x^i in $[-240, 240]$. Our domain sizes are 20^3 , 40^3 and 80^3 , respectively using 70 (8 cores), 380 (8 cores) and 790 (16 cores) CPU hours.

A. Gauge

The gauge choice corresponds to a choice of the lapse function, α , and shift vector, β^i . The metric written in the $(3+1)$ formalism is

$$ds^2 = -\alpha^2 dt^2 + \gamma_{ij}(dx^i + \beta^i dt)(dx^j + \beta^j dt), \quad (1)$$

where γ_{ij} is the spatial metric. Previous cosmological simulations with numerical relativity adopt the synchronous gauge, corresponding to $\alpha = 1$, $\beta^i = 0$ [48, 50]. We instead utilise the general spacetime foliation of [66],

$$\partial_t \alpha = -\alpha^2 f(\alpha) K, \quad (2)$$

where $f(\alpha) > 0$ is an arbitrary function, and $K = \gamma^{ij} K_{ij}$. We set the shift vector $\beta^i = 0$. Harmonic slicing uses $f = \text{const.}$, while $f = 1/\alpha$ corresponds to the “1+log” slicing common in black hole binary simulations. We choose harmonic slicing with $f = 0.25$ to maintain the stability of our evolutions, as in [47]. Harmonic slicing also allows for longer evolutions for the same computational time, compared to 1+log slicing, due to the increased rate of change of the lapse.

B. Perturbative Initial Conditions

Bardeen’s gauge-invariant formalism of cosmological perturbations [67] was developed with the intention to connect metric perturbations to physical perturbations in the Universe. We adopt this formalism in the longitudinal gauge. The general line element of a perturbed, flat FLRW universe, including scalar (Φ, Ψ), vector (B_i) and tensor (h_{ij}) perturbations takes the form

$$ds^2 = -(1 + 2\Psi) dt^2 - \frac{2}{a(t)} B_i dx^i dt + a^2(t) [(1 - 2\Phi) \delta_{ij} + h_{ij}] dx^i dx^j, \quad (3)$$

where $a(t)$ is the FLRW scale factor and δ_{ij} is the identity matrix. We derive initial conditions from the linearly perturbed Einstein equations, implying negligible vector and tensor perturbations [31]. This is valid as long as our simulations begin at sufficiently high redshift that the Universe may be approximated by an FLRW model with small perturbations. Considering only scalar perturbations the metric becomes

$$ds^2 = -(1 + 2\Psi) dt^2 + a^2(1 - 2\Phi) \delta_{ij} dx^i dx^j, \quad (4)$$

where Φ and Ψ are the Bardeen scalar potentials [67]. Here we see that Ψ , the Newtonian potential, will largely influence the motion of non-relativistic particles; where the time-time component of the metric dominates the motion. The Newtonian potential plays the dominant role in galaxy clustering. Relativistic particles will *also* be affected by the curvature potential Φ , and so both potentials influence effects such as gravitational lensing [67, 68].

The metric perturbations are coupled to perturbations in the matter distribution via the stress-energy tensor. We approximate the homogeneous and isotropic background as a perfect fluid in thermodynamic equilibrium, giving

$$T_{\mu\nu} = (\rho + P) u_\mu u_\nu + P g_{\mu\nu}, \quad (5)$$

where ρ is the total energy density, P is the pressure and $u^\mu = (1/\alpha, u^i)$ is the 4-velocity of the fluid. We have

$$u^i \equiv \frac{dx^i}{d\tau} = \frac{dt}{d\tau} \frac{dx^i}{dt} = \frac{1}{\alpha} v^i, \quad (6)$$

where v^i is the 3-velocity. We assume a dust universe, implying negligible pressure ($P \ll \rho$), and we solve the perturbed Einstein equations,

$$\delta G_{\mu\nu} = 8\pi \delta T_{\mu\nu}, \quad (7)$$

using linear perturbation theory. From the time-time, time-space, trace and trace free components of (7), we

obtain the following system of equations [31, 69]

$$\nabla^2 \Phi - 3\dot{a}a \left(\dot{\Phi} + H\Psi \right) = 4\pi\bar{\rho}\delta a^2, \quad (8a)$$

$$H\partial_i \Psi + \partial_i \dot{\Phi} = -4\pi\bar{\rho}a^2\delta_{ij}\delta v^j, \quad (8b)$$

$$\ddot{\Phi} + H \left(\dot{\Psi} + 3\dot{\Phi} \right) = \frac{1}{2a^2} \nabla^2 (\Phi - \Psi), \quad (8c)$$

$$\partial_{(i}\partial_{j)} (\Phi - \Psi) = 0. \quad (8d)$$

Here $H \equiv \dot{a}/a$ is the Hubble parameter, $\partial_i \equiv \partial/\partial x_i$, $\nabla^2 = \partial^i \partial_i$, $\partial_{(i}\partial_{j)} \equiv \partial_i \partial_j - 1/3 \delta_{ij} \nabla^2$, and a dot represents a derivative with respect to the time coordinate t . The quantity $|\Phi - \Psi|$ is known as the gravitational slip [54, 55, 68], which is zero in the linear regime and in the absence of anisotropic stress. At higher orders in perturbation theory, the gravitational slip is non-zero, and $\Phi \neq \Psi$ [see e.g. 70].

We perturb the matter by making the substitutions

$$\rho = \bar{\rho}(1 + \delta), \quad (9a)$$

$$v^i = \delta v^i, \quad (9b)$$

where $\bar{\rho}$ represents the background FLRW density. We derive the relativistic fluid equations from the components of the energy-momentum conservation law,

$$\nabla_\alpha T_\mu{}^\alpha = 0, \quad (10)$$

where ∇_α is the covariant derivative associated with the 4-metric. The resulting continuity and Euler equations are,

$$\dot{\delta} = 3\dot{\Phi} - \partial_i v^i, \quad (11a)$$

$$2Hv^i + \dot{v}^i = -\partial^i \Psi. \quad (11b)$$

III. FLRW SPACETIME

We test our thorn `FLRWSolver` together with the Einstein toolkit on two analytic solutions to Einstein's equations relevant to cosmology. Our first and simplest test is the flat, dust FLRW model. Here we initialise a homogeneous and isotropic matter distribution and spatial metric, and evolve in the harmonic gauge, as outlined in section II A. While the Einstein Toolkit has been previously tested on FLRW and Kasner cosmologies [52, 71], this is an important first test of `FLRWSolver` and its interaction with the evolution thorns.

A. Setup

The line element for a spatially homogeneous and isotropic flat FLRW spacetime is given by

$$ds^2 = -\alpha^2 dt^2 + \frac{a^2(t)}{(1 + kr^2/4)^2} \delta_{ij} dx^i dx^j, \quad (12)$$

where $k = -1, 0, 1$ if the universe is open, flat or closed respectively. Assuming homogeneity and isotropy Einstein's equations reduce to the Friedmann equations [72, 73],

$$\left(\frac{\dot{a}}{a} \right)^2 = \frac{8\pi\rho}{3} - \frac{k}{a^2}, \quad (13a)$$

$$\dot{\rho} = -3\frac{\dot{a}}{a}(\rho + P). \quad (13b)$$

Here we assume a flat spatial geometry, supported by combined Planck and Baryon Acoustic Oscillation data [74]. The flat ($K = 0$), dust ($P \ll \rho$) solution to (13) is given by

$$\frac{a}{a_{\text{init}}} = s^{2/3}, \quad \frac{\rho}{\rho_{\text{init}}} = s^{-2}, \quad (14)$$

where $a_{\text{init}}, \rho_{\text{init}}$ are the values of a, ρ at $t = 0$ respectively, and we have introduced the scaled time coordinate,

$$s \equiv 1 + \sqrt{6\pi\rho^*} t, \quad (15)$$

and $\rho^* = \rho a^3$ is the conserved (constant) comoving density for an FLRW universe. We initialise a homogeneous and isotropic matter distribution by specifying constant density $\rho_{\text{init}} = 10^{-8}$ and zero velocity in `FLRWSolver`, with $a_{\text{init}} = 1$. The Einstein Toolkit then initialises the stress-energy tensor, coupled to our homogeneous and isotropic spacetime, characterised by the spatial metric, $\gamma_{ij} = a^2(t)\delta_{ij}$, and extrinsic curvature, also set in `FLRWSolver`. We define the extrinsic curvature via the relation

$$\frac{d}{dt} \gamma_{ij} = -2\alpha K_{ij}, \quad (16)$$

where $d/dt = \partial/\partial t - \mathcal{L}_\beta$, and \mathcal{L}_β is the Lie derivative with respect to the shift vector. Since $\beta^i = 0$, we have $d/dt = \partial/\partial t$. The extrinsic curvature for our FLRW setup is therefore

$$K_{ij} = -\frac{\dot{a}a}{\alpha} \delta_{ij}. \quad (17)$$

We evolve the system in the harmonic gauge until the domain volume has increased by one million, corresponding to a change in redshift of ~ 100 .

B. Results

Figure 1 compares our numerical relativity solutions with the exact solutions to the Friedmann equations. The top panels show the time evolution of a and ρ (dashed magenta curves) relative to their initial values, which may be compared to the exact solutions, a_{FLRW} and ρ_{FLRW} (black solid curves). The bottom panels show the residuals in our numerical solutions at resolutions of 20^3 , 40^3 and 80^3 . The error can be seen to decrease

FIG. 1: Comparison between our numerical simulations (magenta) and the exact solutions (black) for a dust FLRW universe. Top: evolution of the scale factor, a (left) and the density, ρ (right), relative to their initial values a_{init} and ρ_{init} , as a function of time. Bottom: errors in the FLRW scale factor (left) and density (right) at domain sizes 20^3 , 40^3 and 80^3 .

FIG. 2: Fourth-order convergence in the FLRW calculations, showing L_1 error as a function of resolution for the scale factor (left), density (middle), and Hamiltonian constraint (right). N refers to the number of grid points along one spatial dimension. Filled circles indicate data points from our simulations, dashed lines join these points, and black solid lines indicate the expected N^{-4} convergence.

when the spatial resolution is increased. The increase in spatial resolution causes the timestep to decrease via the Courant condition. To quantify this, we compute the L_1 error, given by (e.g. for the scale factor)

$$L_1(a) = \frac{1}{n} \sum_{i=1}^n \left| \frac{a}{a_{\text{FLRW}}} - 1 \right|, \quad (18)$$

where n is the total number of timesteps. As outlined in Section II, we expect fourth-order convergence due to the spatial homogeneity. Figure 2 demonstrates this is true for the scale factor (left), density (middle) and the Hamiltonian constraint (right),

$$H \equiv {}^{(3)}R - K_{ij}K^{ij} + K^2 - 16\pi\rho = 0, \quad (19)$$

where ${}^{(3)}R$ is the 3-Riemann scalar and $K = \gamma^{ij}K_{ij}$. For the FLRW model this reduces to the first Friedmann equation (13a).

The results of this test demonstrate that the Einstein Toolkit, in conjunction with our initial-condition thorn **FLRWSolver**, produces agreement with the exact solution for a flat, dust FLRW spacetime, with relative errors less than 10^{-6} , even at low spatial resolution (80³).

IV. LINEAR PERTURBATIONS

For our second test we introduce small perturbations to the FLRW model. The evolution of these perturbations in the linear regime can be found by solving the system of equations (8). We use these solutions (derived below) to set the initial conditions.

A. Setup

In the absence of anisotropic stress we have $\Psi = \Phi$. Equation (8c) then becomes purely a function of Φ and the FLRW scale factor a . Solving this gives

$$\Phi = f(x^i) - \frac{3}{5} g(x^i) s^{-5/3}, \quad (20)$$

where f, g are functions of only the spatial coordinates. We substitute (20) into the Hamiltonian constraint, Equation (8a), to give the fractional density perturbation $\delta \equiv \delta\rho/\bar{\rho}$, in the form

$$\begin{aligned} \delta = & C_1 s^{2/3} \nabla^2 f(x^i) - 2 a_{\text{init}}^3 f(x^i) \\ & + C_2 s^{-1} \nabla^2 g(x^i) - \frac{9 a_{\text{init}}^3}{5} s^{-5/3} g(x^i), \end{aligned} \quad (21)$$

where we have defined

$$C_1 \equiv \frac{a_{\text{init}}}{4\pi\rho^*}, \quad C_2 \equiv -\frac{3 a_{\text{init}}}{20\pi\rho^*}. \quad (22)$$

Using the momentum constraint, Equation (8b), the velocity perturbation δv^i is therefore

$$\delta v^i = C_3 s^{-1/3} \partial^i f(x^i) + C_4 s^{-2} \partial^i g(x^i), \quad (23)$$

where we have

$$C_3 \equiv -\frac{a_{\text{init}}}{\sqrt{6\pi\rho^*}}, \quad C_4 \equiv -\frac{9 a_{\text{init}}}{10\sqrt{6\pi\rho^*}}. \quad (24)$$

Equation (21) demonstrates both a growing and decaying mode for the density perturbation [67, 75]. We set $g(x^i) = 0$ to extract only the growing mode, giving

$$\Phi = f(x^i), \quad (25a)$$

$$\delta = C_1 s^{2/3} \nabla^2 f(x^i) - 2f(x^i), \quad (25b)$$

$$\delta v^i = C_3 s^{-1/3} \partial^i f(x^i), \quad (25c)$$

from which we set our initial conditions. We choose

$$\Phi = \Phi_0 \sum_{i=1}^3 \sin\left(\frac{2\pi x^i}{L}\right), \quad (26)$$

where L is the length of one side of our computational domain. We require the amplitude $\Phi_0 \ll 1$ so that our assumptions of linearity are valid, and so we set $\Phi_0 = 10^{-8}$. This choice then sets the form of our density and velocity perturbations, as per (25b) and (25c). At $t = 0$ ($s = 1$) these are,

$$\delta = \left[\left(\frac{2\pi}{L} \right)^2 C_1 - 2 \right] \Phi_0 \sum_{i=1}^3 \sin\left(\frac{2\pi x^i}{L}\right), \quad (27)$$

$$\delta v^i = \frac{2\pi}{L} C_3 \Phi_0 \sum_{i=1}^3 \cos\left(\frac{2\pi x^i}{L}\right), \quad (28)$$

and the choice of Φ_0 results in amplitudes of $\delta \sim 10^{-5}$ and $\delta v^i \sim 10^{-7}$. We set these matter perturbations in **FLRWSolver**, assuming negligible pressure and again using (16) to define the extrinsic curvature. For a linearly perturbed FLRW spacetime with $\Psi = \Phi$ and $\dot{\Phi} = 0$ we have

$$K_{ij} = -\dot{a}a \frac{1 - 2\Phi}{\sqrt{1 + 2\Phi}} \delta_{ij}. \quad (29)$$

We evolve these perturbations in the harmonic gauge until the volume of the domain has increased by 125 million, $(\Delta a)^3 \sim 1.25 \times 10^8$, corresponding to a factor of 500 change in redshift.

B. Results

Dashed magenta curves in Figure 3 show the time evolution of the fractional density perturbation, $\delta \equiv \delta\rho/\bar{\rho}$ (top left), and the velocity perturbation, δv (top right). Solid black curves show the exact solutions (25b) for δ_{exact} and (25c) for δv_{exact} . Bottom panels show the relative errors for three different resolutions. Figure 4 shows the L_1 error as a function of resolution, demonstrating the expected second-order convergence. Figure 5 shows the Hamiltonian (top), and momentum (bottom) constraints as a function of time at our three chosen resolutions. The Hamiltonian constraint was defined in Equation (19). For our linearly perturbed FLRW spacetime this reduces to Equation (8a). The momentum constraint is

$$M_i \equiv D_j K^j_i - D_i K - S_i = 0, \quad (30)$$

where D_j is the covariant derivative associated with the 3-metric, and the matter source $S_i = -\gamma_{i\alpha} n_\beta T^{\alpha\beta}$, with n_β the normal vector [62]. For linear perturbations this constraint reduces to Equation (8b). Figure 5 shows a better preservation of the Hamiltonian constraint with increasing resolution. The momentum constraint shows

FIG. 3: Comparison between our numerical relativity solutions and exact solutions for the linear perturbations to a dust FLRW model. We show the time evolution of the fractional density perturbation (top left) and the velocity perturbation (top right) computed from one-dimensional slices along the x axis of our domain. Bottom: relative errors for calculations at 20^3 , 40^3 and 80^3 .

FIG. 4: Second order convergence of our numerical solutions to the exact solutions for a linearly perturbed FLRW spacetime, showing L_1 errors in the density (left) and velocity perturbations (right). N refers to the number of grid points along one spatial dimension. Filled circles indicate data points from our simulations, dashed lines join these points, and black solid lines indicate the expected N^{-2} convergence.

the opposite. We attribute this to the momentum constraint being preserved to of order the roundoff error, which will become larger with an increase in resolution. Even at the highest resolution the momentum constraint is preserved to within 10^{-15} .

This second test has demonstrated a match to within

$\sim 10^{-3}$ of our numerical relativity solutions to the exact solutions for the linear growth of perturbations, while exhibiting the expected second-order convergence.

FIG. 5: Maximum value (anywhere in the domain) of the Hamiltonian (top panel) and momentum (bottom panel) constraints in the evolution of a linearly perturbed FLRW space-time, shown at resolutions 20^3 , 40^3 and 80^3 .

V. NONLINEAR EVOLUTION

In order to evolve our perturbations to nonlinear amplitude in a reasonable computational time, we increase the size of our initial perturbations to $\Phi_0 = 10^{-6}$, which in turn gives $\delta \sim 10^{-3}$ and $\delta v^i \sim 10^{-5}$. The linear approximation remains valid.

We choose the starting redshift to be that of the cosmic microwave background (CMB). That is, we set $z = 1000$, such that our initial density perturbation is roughly consistent with the amplitude of temperature fluctuations in the CMB ($\sim 10^{-5}$) [76]. We emphasise that this redshift, and all redshifts shown in figures, should not be taken literally; its purpose is to assign an approximate *change* in redshift, calculated directly from the FLRW scale factor.

A. Results

Figure 6 shows a series of one-dimensional slices through the origin of the y and z axes at four different times. Dashed magenta curves show solutions for the density (top row) and velocity (bottom row) perturbations, which may be compared to the black solid curves showing the analytic solutions for linear perturbations. At $t = 0$ and $t = 1.2 \times 10^5$ (first and second columns respectively) the solutions are linear, while at $t = 2.3 \times 10^6$ (third column) both the density and velocity perturbations deviate from linear theory. The perturbations are nonlinear at $t = 1.7 \times 10^7$ (fourth column) where matter collapses towards the overdensity, indicated by the shift in the maximum velocity.

The final column shows an apparent decrease in the

average density. This is an artefact of taking a one-dimensional slice through a three-dimensional box. Figure 7 shows the column-density perturbation, δ_{col} , computed by integrating the density perturbation along the z axis. Panels show $t = 0$ and $t = 1.7 \times 10^7$ respectively. The right panel shows an increase of ~ 3000 times in the column-density perturbation at $x, y \approx -120, 120$. A corresponding void can be seen in the lower right of Figure 7, explaining the underdensity along the y axis seen in the final column of Figure 6.

Figure 8 shows the maximum value of the density (left) and velocity (right) perturbations as a function of time. Dashed magenta curves show the numerical solutions, which may be compared to the black curves showing the linear analytic solutions. Perturbations can be seen to deviate from the linear approximation at $t \approx 10^6$, when $\delta\rho/\bar{\rho} \approx 0.1$. At $t \approx 10^7$, the maximum of the density and velocity perturbations have respectively grown 25 and 2 times larger than the linear solutions.

B. Gravitational slip and tensor perturbations

Gravitational slip is defined as the difference between the two potentials Φ and Ψ [54, 55], which is zero in the linear regime, see equation (8d), but nonzero in the nonlinear regime [see e.g. 70]. We reconstruct Φ and Ψ from the metric components. From (3) the spatial metric is

$$\gamma_{ij} = a^2 [(1 - 2\Phi)\delta_{ij} + h_{ij}], \quad (31)$$

and we adopt the traceless gauge condition $\delta^{ij}h_{ij} = 0$ [30, 31]. The potential Φ is then

$$\Phi = \frac{1}{2} \left(1 - \frac{\delta^{ij}\gamma_{ij}}{3a^2} \right), \quad (32)$$

which holds for all times the metric (3) applies. The potential Ψ is more complicated: our gauge choice implies lapse evolution according to (2), where we have set $f(\alpha) = 1/4$, and

$$K = -3 \frac{\dot{a}}{a\alpha}, \quad (33)$$

in the linear regime, which gives

$$\dot{\alpha} = \frac{3}{4} \frac{\dot{a}}{a}. \quad (34)$$

Integrating this results in a lapse evolution of

$$\alpha = D(x^i) a^{3/4}, \quad (35)$$

where $D(x^i)$ is a function of our spatial coordinates. According to the metric (4), this implies

$$\alpha = a^{3/4} \sqrt{1 + 2\Psi}, \quad (36)$$

FIG. 6: Density (top row) and velocity (bottom row) perturbations as a function of position within our domain. Here we show one-dimensional slices of our 40^3 domain during the evolution. All quantities are shown in code units. Dashed magenta curves show our numerical solutions, and black solid curves show the exact solutions for the linear regime. Initial data ($t = 0$; first column) and $t = 1.2 \times 10^5$ (second column) match linear theory. We see a clear deviation from linear theory at $t = 2.3 \times 10^6$ (third column) and $t = 1.7 \times 10^7$ (fourth column). Simulation redshifts are shown as an indicator of the *change* in redshift.

FIG. 7: Column-integrated density perturbation showing the gravitational collapse of an overdense region. The two panels correspond to the left and right panels of Figure 6 respectively, at times of $t = 0$ and $t = 1.7 \times 10^7$. All quantities are shown in code units for our 40^3 simulation. Grey dashed lines indicate the position of the one-dimensional slices shown in Figure 6.

from which we reconstruct the potential Ψ to be

$$\Psi = \frac{1}{2} \left[\left(\frac{\alpha}{a^{3/4}} \right)^2 - 1 \right], \quad (37)$$

valid in the linear regime. Our gauge choice $\beta^i = 0$ implies that in the nonlinear regime we expect additional modes to be present in this reconstruction of Ψ .

We use an FLRW simulation for the scale factor a in

(32) and (37), from which we calculate the gravitational slip $|\Phi - \Psi|$. Figure 9 shows one-dimensional slices of the gravitational slip at the same times as was shown in Figure 6. Dashed curves show the numerical results, with black lines showing the linear solution; zero gravitational slip. In the fourth panel ($t = 1.7 \times 10^7$) we see a positive shift of the gravitational slip to $\approx 5 \times 10^{-6}$ for this one-dimensional slice, with the maximum value in

FIG. 8: Nonlinear growth of the density (left) and velocity (right) perturbations. Dashed magenta curves show the maximum value within the domain as a function of time (in code units), while black solid curves show the analytic solutions for linear growth. Here we show the simulation with domain size 40^3 . Blue circles represent the times of the ($t > 0$) panels shown in Figure 6.

FIG. 9: One-dimensional slices of the gravitational slip over time. Dashed magenta curves show numerical solutions for a 40^3 domain, while black solid lines show the solution for linear perturbation theory; zero. The potentials Φ and Ψ are reconstructed according to (32) and (37) respectively. Initial data ($t = 0$) is shown in the left column, and time increases towards the right as indicated by timestamps. We show the simulation redshift as an indicator of the approximate *change* in redshift only, and all quantities here are shown in code units.

the domain being 6.5×10^{-6} . The Newtonian potential Ψ has a positive average value at $t = 1.7 \times 10^7$, due to the majority of the domain being underdense (see Figure 7), and the potential Φ takes a negative average value. This can be interpreted as an overall positive contribution to the expansion, from the metric (3).

Relativistic corrections to one-dimensional N-body simulations in [31] resulted in a gravitational slip of 5×10^{-6} . We show a gravitational slip of the same amplitude, including the full effects of general relativity in a three-dimensional simulation, for a time when our density perturbation is comparable in size to that of [31]. Gravitational slip is a measurable effect that can be quantified by combining weak gravitational lensing and galaxy clustering [68]. Our simulations show tentative evidence

for the importance of gravitational slip due to nonlinear gravitational effects. However, robust predictions require higher resolution simulations with more realistic initial conditions.

In our initial conditions we neglected vector and tensor perturbations in the perturbed FLRW metric (3), since in the linear regime the scalar perturbations dominate. These higher order perturbations appear in the nonlinear regime. The tensor perturbation can be directly extracted from the off-diagonal, spatial components of the metric,

$$\gamma_{ij} = a^2 h_{ij} \quad \text{for } i \neq j, \quad (38)$$

where we calculate h_{ij} using the value of a as per the scalar perturbations.

FIG. 10: Two-dimensional slice of the xy component of the tensor perturbation h_{ij} at $t = 1.7 \times 10^7$. We use (38) to calculate h_{xy} using the off-diagonal metric component g_{xy} . All quantities are shown in code units for our 40^3 simulation.

Figure 10 shows a two-dimensional cross-section of the xy component of the tensor perturbation h_{ij} . All other components are identical. The cross-section is shown at $t = 1.7 \times 10^7$, corresponding to the right panel of Figures 6, 7 and 9. While the maximum amplitude of the tensor perturbation is small ($\sim 2 \times 10^{-6}$), an asymmetry develops in h_{xy} , corresponding to the location of the overdensity in Figure 7. We also see a diffusion of the tensor perturbation in the void, indicating the beginning of growth of higher order perturbations.

VI. DISCUSSION AND CONCLUSIONS

We have demonstrated the feasibility of inhomogeneous cosmological simulations in full general relativity using the Einstein Toolkit. The overall approach is similar to other recent attempts [48, 50], with the main difference being in the construction of initial conditions which allows us to simulate a pure growing mode, instead of a mix of growing and decaying modes [see 77]. We also use a different code to [48], allowing for independent verification. As with the other studies we were able to demonstrate the evolution of a density perturbation into the nonlinear regime.

As this is a preliminary study, we have focused on the numerical accuracy and convergence, rather than a detailed investigation of physical effects such as backreaction. Our main conclusions are:

1. We demonstrate fourth-order convergence of the numerical solution to the exact solution for a flat, dust FLRW universe with errors $\sim 10^{-5}$ even at low spatial resolution (40^3).
2. We demonstrate second-order convergence of the numerical solutions for the growth of linear perturbations, matching the analytic solutions for the cosmic evolution of density, velocity and metric perturbations to within $\sim 10^{-3}$.
3. We show that numerical relativity can successfully be used to follow the formation of cosmological structures into the nonlinear regime. We demonstrate the appearance of non-zero gravitational slip and tensor modes once perturbations are nonlinear with amplitudes of $\sim 5 \times 10^{-6}$ and $\sim 2 \times 10^{-6}$ respectively.

The main limitation to our study is that we have employed only low-resolution simulations compared to current Newtonian N-body cosmological simulations [e.g. 1–3], and used only simple initial conditions rather than a more realistic spectrum of perturbations [but see 48]. Representing the density field on a grid means our simulations are limited by the formation of shell-crossing singularities. The relative computational expense means that general relativistic simulations are unlikely to replace the Newtonian approach in the near future. However, they are an important check on the accuracy of the approximations employed.

Acknowledgements

We thank Bruno Giacomazzo and the organisers of the Einstein Toolkit Summer Workshop in June 2016 for their advice and support, specifically Eloisa Bentivegna for valuable conversations and Wolfgang Kastaun for support with his visualisation package for Cactus. We thank Todd Oliynyk, Krzysztof Bolejko, Tamara Davis, Chris Blake, Greg Poole, David Wiltshire and Robert Wald for useful discussions. We used the Riemannian Geometry & Tensor Calculus (RGTC) package for Mathematica, written by Sotirios Bonanos. Our simulations were performed on the Multi-modal Australian ScienceS Imaging and Visualisation Environment (MASSIVE) M2 facility located at Monash University. DJP and PDL gratefully acknowledge funding from the Australian Research Council (ARC) via Future Fellowship FT130100034 and Discovery Project DP1410102578, respectively.
